

Docker is good for creating similar environments for everyone in the team and for the cloud server. For example, in testing perspective to deploy same typescript and node version, deploy same browser versions. After it we can automate the build, deploy or test running commands. This way we won't meet with that case it worked for me in local environment, but it failed on the server as we have the same environment. If we use blacklisted or whitelisted IP addresses, then it still can happen.

CI tool: in Azure Devops we can create different tasks for applications build and deploy and test running. For test running we can have different methods, like running smoke tests after every code push and deploy and run regression pack daily. So for this we can set trigger points, e.g. the smoke job trigger is the product deployment. The main steps can be the git clone, type check, format check, clean code check, build and run unit tests and deploy products, if all of them passed then can start the test job for API or UI tests.
